Abstract. An approach to the 3D intelligent video surveillance based on the means of the object-oriented logic programming is proposed. In contrast to the conventional 2D video surveillance, the methods of 3D vision provide reliable recognition of parts of the human body that makes possible a new statement of the problem and efficient practical application of methods of people behaviour analysis in the video surveillance systems. The logic-based approach to the intelligent video surveillance allows easy definition of people complex behaviour in terms of simpler activities and postures. The goal of this work is to implement the advantages of the logic programming approach in the area of 3D intelligent video surveillance.

1. INTRODUCTION

The 3D video surveillance term has different meanings in research papers:

1. Initially, this term was associated with advanced video surveillance systems supporting real-time 3D visualization of indoor environment, buildings, and people to be monitored, as well as application of virtual and augmented reality technologies in the video surveillance [1]–[4].

2. This term could be associated also with so-called 3D approaches to motion recovery from 2D images [5].

Nowadays, this term could be associated with using 3D/2.5D data acquisition equipment [6] like time-of-flight (ToF) cameras, structured light sensors, stereo cameras, laser scanners (LiDARs) [7], and Flash Ladars [8] in video surveillance. Availability of 3D data acquisition equipment leads to considerable progress in video surveillance related research areas such as background subtraction and tracking people [9], [10], person identification [11], [12], face recognition [13], posture recognition [14], [15], gesture recognition [16], people counting [17], human activity recognition [18], etc. because the use of the 3D/2.5D data makes possible to solve many complicated problems of computer vision caused by the presence of shadows, variations in illumination, view-point changes, cluttered background, and occlusions. And a more important point is in that this technological advance enables progress in solving complex intelligent video surveillance problems [19].
like human-human interaction recognition and prediction [20], abnormal event detection for healthcare systems [21]-[23], unusual events detection [24], the behaviour of customers [25], monitoring of people with disabilities [26], [27], aggressive behaviour and anger detection [28], gait recognition [29] and biometric surveillance [30], and analyzing the human motion to aid clinical decision making [31], [32].

In contrast to the conventional 2D video surveillance, the methods of 3D vision provide reliable recognition of the parts of the human body that makes possible a new statement of the problem and efficient practical application of methods of people behaviour analysis in the video surveillance systems. According to [33], people behaviour is a kind of activity which is a response to some stimuli (internal, external, conscious, or unconscious). For example, such interactions of people as a friendly handshake, a fight, the stealing of a suitcase from another person, etc. could be forms of behaviour. Analysis of the behaviour requires information about the context and other factors influencing it [33]. This information can include video scene geometry, place and presence of objects, time constraints, etc. Thus, the availability of exact information about the co-ordinates of the parts of the body and scene geometry provided by means of the 3D vision is a key to the automation of people behaviour analysis, recognition, and understanding.

Mathematical logic and logic programming were recognized as convenient means for video scene context description and analysis. The idea of the logic programming based approach to the people behaviour analysis is in usage of logical rules for description and analysis of people activities. Knowledge about the human body structure, object properties, time constraints, and scene geometry is encoded in the form of the rules in a logic language and is applied to the output data of some low-level procedures of detection of people and objects.

This idea was developed in the framework of the conventional 2D intelligent video surveillance, and there are a lot of studies based on it. The usage of temporal logic programs in the W4 real-time system for representation of actions and analysis of people movements was reported in [34]. The VidMAP video surveillance system that combines real-time computer vision algorithms with the Prolog-based logic programming had been announced in [35]. Later this research group has proposed an extension of the predicate logic with the bilattice formalism that permits processing of uncertainty in the reasoning about the video scenes [36]. The VERSA general purpose framework for defining and recognizing events in live or recorded surveillance video streams was described in [37]. The VERSA system is based on SWI-Prolog. A real-time complex audio-video event detection based on the Answer Set Programming approach was proposed in [38]. Heuristic rules based on a temporal logic are used for describing semantics of video scenes in [39]. A system [40] was designed for recognition of so-called long-term activities (such as "fight" or "meeting") consisting of sequences of short-term activities (such as "walking", "running", "active movement on the spot", "standstill", and "sharp movements") using a logic programming implementation of the Event Calculus. Later this approach was extended to handle the uncertainty that occurs in human activity recognition [41]. The ProbLog probabilistic logic language was used for this purpose. A Prolog-based video surveillance framework for robust detecting abandoned objects was described in [42]. It is believed that the system automatically identifies interrelations between the observed people in order to draw a conclusion about who exactly owns the observed objects, and thus reduce the probability of a false alarm.

Curiously there are not so many papers that utilize logic programming for 3D video data processing. The method of recognition of
long-term activities [40] was adapted [26] for processing the data collected with the help of Kinect. The monitoring system is intended for the analysis of the behaviour of a person in a support room. As reported in [26], the skeleton data were not used for the analysis of long-term activities though the author calculates so-called Activity Level coefficient on the base of the average displacement of all tracked and inferred joints of the skeleton. The probabilistic approach to the long-term activity recognition [41] was adapted to the development of a distributed monitoring system [43] that provides health-care assistance in a smart home setting. A reasoning engine based on the Description Logics (DL) formalism was used for Kinect-based posture and gesture recognition [44]. Prolog rules were used in the RoboSherlock system [45] to distinguish between actions such as "take", "put", "fill", "push". The logical inference takes into account context information about the properties of the objects. For example, to recognize the "fill" action, it is necessary to know that the object manipulated by a person is a container, food, or an ingredient [45].

The logic-based approach to the intelligent video surveillance has the following obvious advantages [26]:

1. One can easily incorporate domain knowledge into the recognition process.
2. Reasoning about the behaviour of people can be very difficult, but for the developer of the system of intelligent video surveillance, it always remains fundamentally understandable.
3. One can easily define a complex activity in terms of simpler activities.

Our goal is to implement these advantages of the logic approach in the area of the 3D intelligent video surveillance by means of the object-oriented logic programming.

2. THE OBJECT-ORIENTED LOGIC PROGRAMMING OF THE INTELLIGENT VIDEO SURVEILLANCE SYSTEMS

The method of the object-oriented logic programming of the intelligent video surveillance systems was developed in [46]-[52]. The distinctive features of the method are usage of the Actor Prolog object-oriented logic language [53]-[55] and translation of the logic programs of intelligent video surveillance to the Java language [47], [56]. In Actor Prolog the text of a logic program consists of separate classes [53]. Parallel processes represent a kind of instances of classes [54]. The object-oriented means of the logic language allow one to split a program to interacting parallel processes that implement various stages of image processing and scene analysis while translation to the Java language provides a high performance sufficient for analyzing real-time video, as well as reliability and stability of the work of the intelligent video surveillance software.

A conventional approach to recognition of human activity includes low-level and high-level stages of the video processing. In the case of the 2D video surveillance, the low-level stage includes background subtraction of a video image, detection of people and cars in the video image, construction of the trajectories of moving objects, evaluation of the velocities of the objects, etc. The high-level stage includes logical analysis of graphs of the trajectories that are supplied by the low-level analysis algorithms and displaying the results on the screen [50], [51]. The low-level stage of the video processing is implemented in Java [57] in special built-in classes of Actor Prolog.

Since the 2D video surveillance cannot provide a stable recognition of human body parts in most real-world applications, the graphs are used for describing trajectories of blobs (separated areas of a foreground image). The graphs include information about the coordinates and the velocities of the blobs, as
well as a set of statistical metrics describing the regularity of the motion [48]. The blob motion statistics is collected by the low-level analysis procedures and is used for discrimination of running people, people riding bicycles, and cars in the video scene. Usually simple fuzzy inference is implemented for this purpose on the base of the statistical metrics and standard arithmetical predicates of the logic language.

In the case of the 3D video surveillance, the goals of the low-level video analysis are essentially different. For instance, the standard software of the Kinect 2 time-of-flight camera can provide a ready for use foreground blobs, as well as up to six skeletons of people to be monitored [6], [18], [19], [58]-[61]. Thus, the minimal pre-processing of the data can include just a conversion of the images of the skeletons into the terms of the logic language. The high-level stage of the video data processing can be implemented in accordance with the former principles but the information about the video scene is essentially more complete, that gives an opportunity to infer much more of logical consequences on the semantics of the video scene.

3. AN EXAMPLE OF LOGICAL INFERENCE ON 3D DATA

Let us consider a simple logic program that analyses 3D data collected using the Kinect 2 ToF camera.

The data include depth maps and images of skeletons of people, but the program has to analyze the images of the skeletons only and the depth maps are to be used only for the visualization of the video scene. Each skeleton contains 25 joints of various statuses (See Fig. 1). The statuses of joints of skeleton can be the following:

1. Tracked – the corresponding part of the body is directly observed by the camera.
2. Inferred – the position of the joint is a hypothetical one.
3. Unknown – the device has no information about this joint.

Thus, the following set of domains (data types) can be defined in Actor Prolog to describe the data structures to be processed:

**DOMAINS:**

Skeletons = Skeleton*.

The Skeletons type is a list of elements of the Skeleton type. The Skeleton type is an underdetermined set [53] of Actor Prolog. The names of the elements of the skeleton as well as the names of corresponding types are obvious:

Skeleton = {
    identifier: INTEGER,
    head: SkeletonJoint,
    spine: SkeletonSpine,
    left_arm: SkeletonArm,
    right_arm: SkeletonArm,
    left_leg: SkeletonLeg,
    right_leg: SkeletonLeg
}.

The Skeleton type is an underdetermined set [53] of Actor Prolog. The names of the elements of the skeleton as well as the names of corresponding types are obvious:

SkeletonSpine = {
    neck: SkeletonJoint,
    shoulder: SkeletonJoint,
    mid: SkeletonJoint,
    base: SkeletonJoint
}.

SkeletonArm = {
    shoulder: SkeletonJoint,
    elbow: SkeletonJoint,
    wrist: SkeletonJoint,
    hand: SkeletonJoint,
    tip: SkeletonJoint,
    thumb: SkeletonJoint
}.

Fig. 1. The images of skeletons and depth maps are the input data of the logic program. The depth maps are indicated by colours.
SkeletonLeg = {
    hip: SkeletonJoint,
    knee: SkeletonJoint,
    ankle: SkeletonJoint,
    foot: SkeletonJoint
}.

SkeletonJoint = {
    status: SkeletonJointStatus,
    position: VertexPosition3D,
    orientation: JointOrientation3D
}.

The status of a joint is a symbol. Each joint is characterized by a position in 3D space, i.e. by three numbers, by orientation, i.e. by four numbers, and by two pairs of 2D co-ordinates that correspond to this joint and are obtained from the infrared and colour images:

SkeletonJointStatus = 'TRACKED'; 'INFERRED'; 'UNKNOWN'.

VertexPosition3D = {
    point: Point3D,
    velocity: Point3D,
    acceleration: Point3D,
    mapping1: Point2D,
    mapping2: Point2D
}.

JointOrientation3D = q(
    Numerical,
    Numerical,
    Numerical,
    Numerical).

Point3D = p(Numerical,Numerical,Numerical).

Point2D = p(Numerical,Numerical).

Suppose that images of skeletons are transferred from the device in real time. Let us declare a set of predicates analyzing the 3D data:

PREDICATES:
    imperative:
    analyse_skeletons(Skeletons) - (i);
    nondeterm:
    a_hand_of_a_person(Skeletons,INTEGER,VertexPosition3D)
        - (i,o,o);
    determ:
    is_near_a_head_of_a_colleague(Skeletons,INTEGER,VertexPosition3D)
        - (i,i,i);

The analyse_skeletons predicate checks whether there are at least two persons in the video scene and one person punches in the face another person. If there are such persons, the predicate outputs a message in the screen (see Fig. 2). Here is the definition of the predicate:

CLAUSES:
    analyse_skeletons(S):-
        a_hand_of_a_person(S,Id,P),
        is_near_a_hand_of_a_colleague(S,Id,P),!,
        graphic_window ? draw_text(0.93,0.08,
            "A punch in the face is detected!").
    analyse_skeletons(_).

The a_hand_of_a_person predicate is nondeterministic. This predicate returns co-ordinates of hands of persons recognized in the scene. Note, that in the Actor Prolog language, the == operator corresponds to the = ordinary unification of the standard Prolog.

a_hand_of_a_person([S|_],Id,P):-
    S == {
        identifier:Id,
        left_arm:{
            hand:{
                status:'TRACKED',
                position:P|_}
            }
        }
    |_}.

a_hand_of_a_person([S|_],Id,P):-
    S == {
        identifier:Id,
        right_arm:{
            hand:{
                status:'TRACKED',
                position:P|_}
            }
        }
    |_}.

A punch in the face is detected!

Fig. 2. A punch in the face is detected by the logic program.
The following definition is used for the detection of the punch in the face. Execution of the is_near_a_head_of_a_colleague predicate succeeds, if given 3D coordinates of some person's hand are close enough to the coordinates of the head of another person. The predicate checks whether the person punches in the face of another person, but not in his own face. For brevity, the velocity of the movement of the hand and the duration of the contact are not taken into consideration, but in a real intelligent visual surveillance application these attributes are to be checked to provide acceptable specificity of the recognition procedure.

```prolog
is_near_a_head_of_a_colleague([S|_], Id1, P1):-
  S == {
    identifier:Id2,
    head:{
      status:'TRACKED',
      position:P2|_}
  |_},
  Id1 <> Id2,
  is_near(P1,P2),!.

is_near_a_head_of_a_colleague([S|_], Id1, P1):-
  S == {
    identifier:Id2,
    head:{
      status:'TRACKED',
      position:P2|_}
  |_},
  Id1 <> Id2,
  is_near(P1,P2),!.
```

For brevity, predicates implementing the data transferring from the outer world into the program are not considered here. One can find a detailed example of this kind in [50]. The analyse_skeletons predicate is to be called from time to time in the logic program to analyze images of skeletons recognized in 3D video frames transferred from the outside.

Note that the key point of this example is not recognition of the punch in the face (or recognition of a handshaking) that is a simple problem, but in that much more complex logical formulae can be automatically checked in the same way. For example, a logic program can check whether a person shakes hands with all people in the room or not, i.e. a program can make some conclusions on the social status of the person or social relations between all the people in the room. The same technique can be used to solve urgent problems of intelligent visual surveillance, such as recognizing armed attacks, demonstrating threatening poses, robberies, etc.

4. CONCLUSION

A method of the logic object-oriented programming for processing the data obtained from the equipment for 3D data acquisition in the intelligent video surveillance systems was developed. The Actor Prolog object-oriented logic language and translation of the logic programs of intelligent video surveillance to the Java language were used. The object-oriented means of the Actor Prolog logic language allow us to split a program into interacting parallel processes that implement various stages of image processing and scene analysis while translation to the Java language provides a high performance sufficient for analyzing real-time video, as well
as reliability and stability of the work of the intelligent video surveillance software. One can download the software for free from the Web Site [52].

The application of methods of the logic object-oriented programming for 3D data processing gives exciting prospects in the area of intelligent video surveillance. Progress in this research area can be achieved by the development of efficient low-level 3D data processing algorithms, logic programming languages and systems for general purpose, and advanced logical methods of 3D data processing.

ACKNOWLEDGMENT
Authors are grateful to Ivan A. Kershner and Renata A. Tolmatcheva for the help in the preparation of 3D video samples and Angelos Barmoutis for his J4K [59] library that was used for the data collection.
